Abstract. Various phase shifters and absorbers can be put into the arms of a double loop neutron interferometer. The mean intensity levels of the forward and diffracted beams behind an empty four plate interferometer of this type have been calculated. It is shown that the intensities in the forward and diffracted direction can be made equal using certain absorbers. In this case the interferometer can be regarded as a 50/50 beam splitter. Furthermore the visibilities of single and double loop interferometers are compared to each other by varying the transmission in the first loop using different absorbers. It can be shown that the visibility becomes exactly 1 using a phase shifter in the second loop. In this case the phase shifter in the second loop must be strongly correlated to the transmission coefficient of the absorber in the first loop. Using such a device homodyne-like measurements of very weak signals should become possible.

1. Introduction

Neutron interferometry is already a well known method for investigation of coherent matter wave properties. Many features of neutron waves have been analyzed such as coherence and post - selection effects, the spinor symmetry, the magnetic Josephson effect, the multi - photon exchange interaction, spin superposition problems, the Aharonov - Bohm effect, topological phases, gravitationally induced quantum interference, the Sagnac effect, the neutron Fizeau effect et cetera [1].

In this paper we concentrate on coherence effects in a double loop interferometer [2],[3]. Fig.(1) describes an extension of a standard three - plate neutron interferometer where a second loop is added by using a second mirror crystal M2 and where various phase shifters Δ and absorbers α can be inserted in each loop. Both loops are coupled via beam (d) and therefore most attention will be given to the action of an absorbing phase shift in this beam. We focus on two phase shifters Δ_d and Δ_f and two absorbers α_d and α_f in beam (d) and (f) respectively because phase shifters or absorbers in beam (b) are of no additional significance.

The paper is organized as follows. In section 2 intensity aspects of the double loop interferometer are considered. In spite of the non symmetric diffraction properties of neutrons in single crystals it can be shown that a 50/50 intensity split-up can be reached using an absorber in loop B. One of the main findings of the analysis of the double loop interferometer in section 3 is that the visibility of K_0 in the forward beam can be made very high (ideally 1), even for very weak input signals. In section 4 the results are discussed in detail taking into account real experimental situations.

The main aim is to find an interaction where small signals transmitted through phase shifter Δ_d can be detected with high precision. In this respect it is a search for homodyne-like detection of weak neutron signals by the constrain that a symmetric beam splitter does not exist in case of diffraction from a crystal. The new system consists of a coupled double loop perfect crystal system and provides a symmetric beam splitting or can serve as a basic of homodyne neutron detection in a similar sense as known for photon beams [4].

2. Intensity aspects

From the dynamical theory of diffraction the wave function behind the analyzer crystal in the forward direction (index 0) which is a superposition of three waves due to the three pathways (s. Fig.(1)) reads as ([1],[5])

$$\psi_0^{(acf)+(adg)+(beg)} = \psi_e e^{i\gamma} v_0^2 v_G v_0' [e^{ik\Delta_f - \alpha_f} + e^{ik\Delta_d - \alpha_d} + 1] \ . \tag{1}$$

In this expression $\psi_e = u_0 e^{i\mathbf{kr}}$ is the incoming plane wave function with amplitude u_0, wave vector $\mathbf{k}$ and position vector $\mathbf{r}$ impinging on the beam splitter S. $e^{i\gamma}$ is a phase

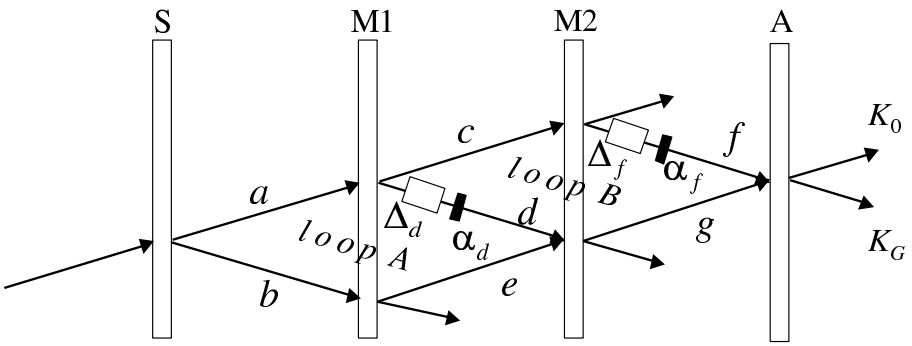

Figure 1. Double loop neutron interferometer: there are three beam pathes: (acf), (adg) and (beg). Δ_d and Δ_f are two phase shifters, α_d and α_f are two absorbers, K_0 and K_G denote the intensity in the forward and diffracted direction respectively. S is the beam splitter crystal, M1 and M2 are two mirror crystals and A is the analyzer crystal. All four crystal plates have the same thickness D and have equal distance from each other. The first loop (loop A) is formed by the beams $(adeb)$, the second loop (loop B) by the beams $(cfgd)$. Beam (g) is a superposition of beam (ad) and beam (be).

factor which is of no relevance in the following. The crystal functions v_0, v_G and v_0' are given as [5]

$$v_0 = e^{iPD}[cos(\bar{A}\sqrt{1+y^2}) + iy\frac{sin(\bar{A}\sqrt{1+y^2})}{\sqrt{1+y^2}}] \ . \tag{2}$$

$$v_G = -ie^{iPD}\frac{sin(\bar{A}\sqrt{1+y^2})}{\sqrt{1+y^2}} \ , \ v_0' = v_G(-y) \ . \tag{3}$$

The index G means the diffracted direction. $P = -\pi(1+y)/\Delta_0$ and $\bar{A} = \pi D/\Delta_0$ where Δ_0 is the Pendelloesung length which is $\Delta_0 = \lambda\, cos(\gamma)/|V(\mathbf{G})/E|$. $\lambda = 2\pi/k$ is the wave length and γ is the angle between the beam direction and the vector perpendicular to the crystal surface. $|V(\mathbf{G})/E| \approx 10^{-6}$ is the ratio between the crystal potential $V(\mathbf{G})$ and the energy E of the particles where $\mathbf{G}$ is the reciprocal lattice vector corresponding to the reflection plane under consideration. $\Delta_0 = 0.00641\, cm$ for the $(2,2,0)-$ reflection of $2\mathring{A}$ neutrons in a silicon single crystal. The quantity $\bar{A}$ is proportional to the crystal thickness D. The quantity y depends on the deviation from the Bragg angle. For symmetric diffraction y is defined as $y = k\, sin(2\theta_B)\,(\theta_B - \theta)/|V(\mathbf{G})/E|$. $y = 0$ gives the exact direction of the Bragg angle $\theta = \theta_B$. The crystal function v_0 describes the diffraction property of the wave function through a single crystal of thickness D. v_G characterizes the case of diffraction due to the dynamical theory. The three terms in Eq.(1) form a superposition of three wave functions which belong to the three pathways (acf), (adg) and (beg). They have different phase shifts and absorptions. The crystal

functions defined above are equal for each of the three wave functions, because each beam is transmitted (function v_0^2) and diffracted (functions v_G and $v_G(-y)$) twice respectively.

The wave function in the diffracted direction behind the analyzer crystal reads

$$\psi_G^{(acf)+(adg)+(beg)} = \psi_{e'} e^{i\delta} v_0 v_G [v_0 v'_G e^{ik\Delta_f - \alpha_f} + v_G v'_0 (e^{ik\Delta_d - \alpha_d} + 1)] \ . \qquad (4)$$

Here, $\psi_{e'} = u_0 e^{i\mathbf{k}_G \mathbf{r}}$ is a plane wave function with wave vector $\mathbf{k}_G$ pointing to the diffracted direction. $e^{i\delta}$ is a phase factor. The crystal function v'_G is equal to $v_0(-y)$. From Eq.(4) it can be recognized that the three wave functions which are superimposed in the forward direction (0) have the same but those in the diffracted direction G do not have the same number of reflections and transmissions. Therefore an unsymmetrical intensity behavior can be expected in the diffracted direction, as shown below.

In order to compute the intensities K_0 and K_G behind the analyzer crystal the squared moduli of the wave functions, i.e. $|\psi_0^{(acf)+(adg)+(beg)}|^2$ and $|\psi_G^{(acf)+(adg)+(beg)}|^2$, have to be taken into account. Because of the thickness of about 0.5 cm of the crystal plates in Fig.(1) the quantity $\bar{A} = \pi D/\Delta_0 >> 1$ cause very rapid oscillations of the terms $sin^{2n}(x)$ which appear in these expressions. Therefore the mean values of these trigonometric functions can be used. One gets: $\overline{sin^2(x)} = 1/2$, $\overline{sin^4(x)} = 3/8$, $\overline{sin^6(x)} = 5/16$ and $\overline{sin^8(x)} = 35/128$ [2]. Moreover integration over the variable y must be performed because of the beam divergence which has to be taken into account. Finally a normalized Gaussian spectral distribution

$$g(k) = \frac{1}{\sqrt{2\pi}(\delta k)} exp[\frac{(k-k_0)^2}{2(\delta k)^2}] \qquad (5)$$

of incoming wave numbers k is assumed. Here k_0 is the mean value and $(\delta k)^2$ is the mean square deviation of wave numbers. The intensities can now be calculated (setting $u_0 = 1$) as follows (the limits of integration are always $-\infty$ and $+\infty$):

$$\begin{aligned} K_0 = \int g(k)[\int \overline{|\psi_0^{(acf)+(adg)+(beg)}|^2} dy]dk = \frac{79\pi}{2048}\{1 + e^{-2\alpha_d} + e^{-2\alpha_f} + \\ +2e^{-\alpha_d} e^{-(\delta k)^2(\Delta_d)^2/2} cos(\Delta_d k_0) + 2e^{-\alpha_f} e^{-(\delta k)^2(\Delta_f)^2/2} cos(\Delta_f k_0) + \\ +2e^{-(\alpha_d+\alpha_f)} e^{-(\delta k)^2(\Delta_d-\Delta_f)^2/2} cos[(\Delta_d - \Delta_f)k_0]\} \ , \end{aligned} \qquad (6)$$

$$\begin{aligned} K_G = \int g(k)[\int \overline{|\psi_G^{(acf)+(adg)+(beg)}|^2} dy]dk = \frac{\pi}{2048}\{65(1 + e^{-2\alpha_d}) + \\ +417e^{-2\alpha_f} + 130e^{-\alpha_d} e^{-(\delta k)^2(\Delta_d)^2/2} cos(\Delta_d k_0) - \\ -158e^{-\alpha_f} e^{-(\delta k)^2(\Delta_f)^2/2} cos(\Delta_f k_0) - \\ -158e^{-(\alpha_d+\alpha_f)} e^{-(\delta k)^2(\Delta_d-\Delta_f)^2/2} cos[(\Delta_d - \Delta_f)k_0]\} \ . \end{aligned} \qquad (7)$$

Fig.(2) plots K_0 and K_G for $\Delta_d = 0$ and $\alpha_d = \alpha_f = 0$ as a function of Δ_f. If $\Delta_f = 0$, $K_0 = 711\pi/2048$ and $K_G = 361\pi/2048$. These results can be found elsewhere [2]. One can recognize that the mean intensities of the two beams are - in general - different (just like in single loop interferometry). The question arises if these intensity levels can be

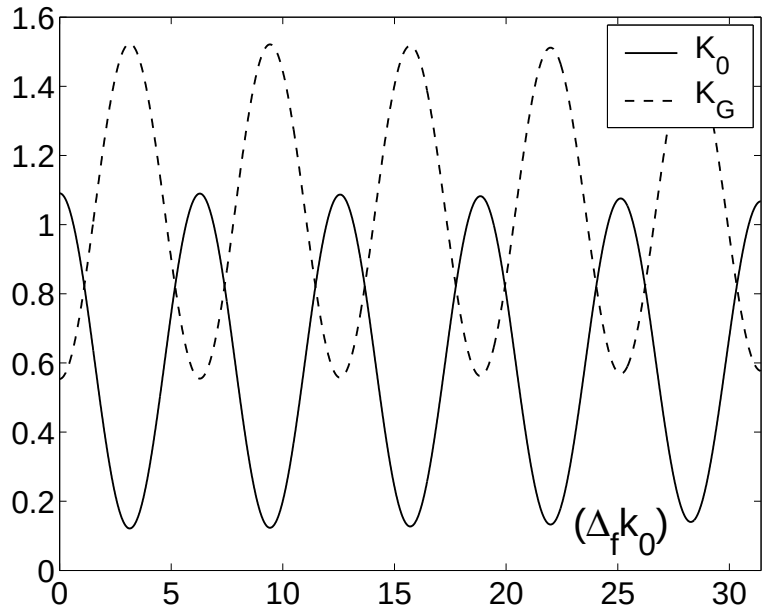

Figure 2. Intensities K_0 and K_G of Eqs.(6) and (7) behind the double loop interferometer (s. Fig.(1)) for $\alpha_d = \alpha_f = 0$, $\Delta_d = 0$ and $(\delta k)/k_0 = 1/100$. The level of oscillations of K_0 is below that of K_G.

made equal by using special parameter values. The answer is yes. If one takes the mean values of K_0 and K_G to be equal, i.e. $\overline{[K_0 - K_G]}_{\Delta_f} = 0$, one gets a condition for α_f:

$$\alpha_f = -\frac{1}{2} ln\{\frac{7}{169}[\,1 + e^{-2\alpha_d} + 2\,e^{-\alpha_d} e^{-(\delta k)^2(\Delta_d)^2} cos(\Delta_d k_0)]\}{\geq}0 \quad . \tag{8}$$

Any absorption α has to be $\geq$0, because the transmission $T = e^{-2\alpha}$ of a beam obeys the relation $0{\leq}T{\leq}1$. In case of $\alpha_d = 0$ and $\Delta_d = 0$, the absorption α_f becomes $-(1/2)ln(28/169) = 0.8988$. Fig.(3) demonstrates this example. In this case the double loop interferometer may be regarded as a 50/50 beam splitter by using an absorption element in a suitable arm of the device. This is not possible using a single loop interferometer.

3. Visibilities of single and double loop interferometers

The visibility is defined as

$$V = \frac{I_{max} - I_{min}}{I_{max} + I_{min}} \quad . \tag{9}$$

We distinguish two kinds of absorption processes: stochastic (sto) and deterministic (det) absorption [6]. In an interferometer stochastic absorption is realized by inserting an absorbing material in one arm of a beam (s. Fig.(1)). Deterministic absorption can be achieved by a chopper which blocks the beam path periodically or by partial reduction of the beam cross section. In the following we investigate the visibility in a single and double loop interferometer at low interference order (coherence function is

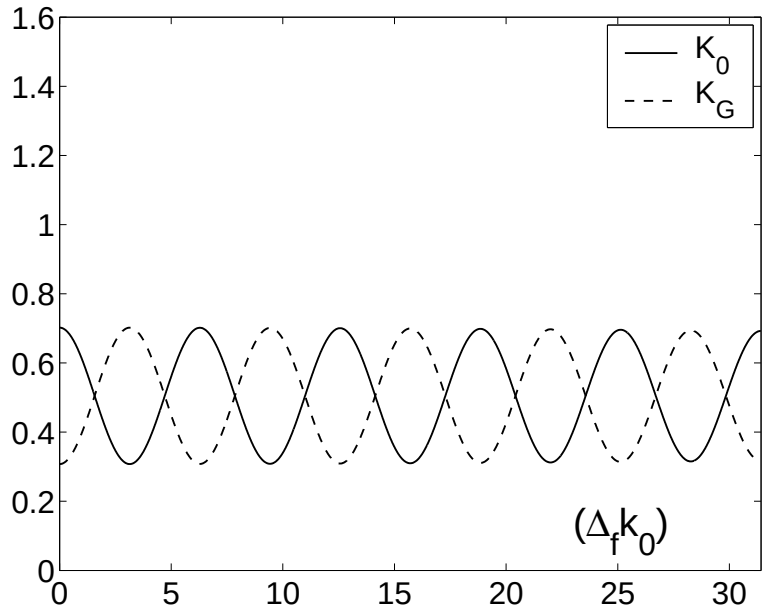

Figure 3. Calculated intensity oscillations of K_0 and K_G of Eqs.(6) and (7) considering the following parameters: $\alpha_d = 0$, $\alpha_f = -(1/2)ln(28/169) = 0.8988$, $\Delta_d = 0$ and $(\delta k)/k_0 = 1/100$. The intensity levels are equal due to α_f.

approximately 1).

a) *Single loop interferometer (index 1)*: If one phase shifter Δ_d and one absorber α_d is put in beam path (d), the intensity I_0 in the forward direction can be written as

$$I_0 \propto |\, 1 + e^{ik_0\Delta_d - \alpha_d}|^2 = 1 + T_d + 2\sqrt{T_d}\, cos(\Delta_d k_0) \quad , \tag{10}$$

where $T_d = e^{-2\alpha_d}$ is the transmission probability of beam (d) and $\Delta_d k_0$ is the phase difference between the two beam paths. The visibility is therefore

$$V_{sto1} = \frac{2\sqrt{T_d}}{1 + T_d} \quad . \tag{11}$$

For deterministic absorption we get

$$I_0 \propto |\, 1 + e^{ik_0\Delta_d}|^2 T_d + (\, 1 - T_d) = 1 + T_d + 2\, T_d\, cos(\Delta_d k_0) \quad , \tag{12}$$

$$V_{det1} = \frac{2\, T_d}{1 + T_d} \quad . \tag{13}$$

The difference between stochastic and deterministic absorption in a single loop neutron interferometer is drawn in Fig.(4) and has been discussed in [6].

b) *Double loop interferometer (index 2)*: If Δ_d and α_d is placed in path (d) and no phase shifter or absorber in beam path (f) (see Fig.(1)), the intensity is given as (see Eq.(6)):

$$K_0 \propto |\, 2 + e^{ik_0\Delta_d - \alpha_d}|^2 = T_d + 4\,[\, 1 + \sqrt{T_d}\, cos(\Delta_d k_0)] \quad , \tag{14}$$

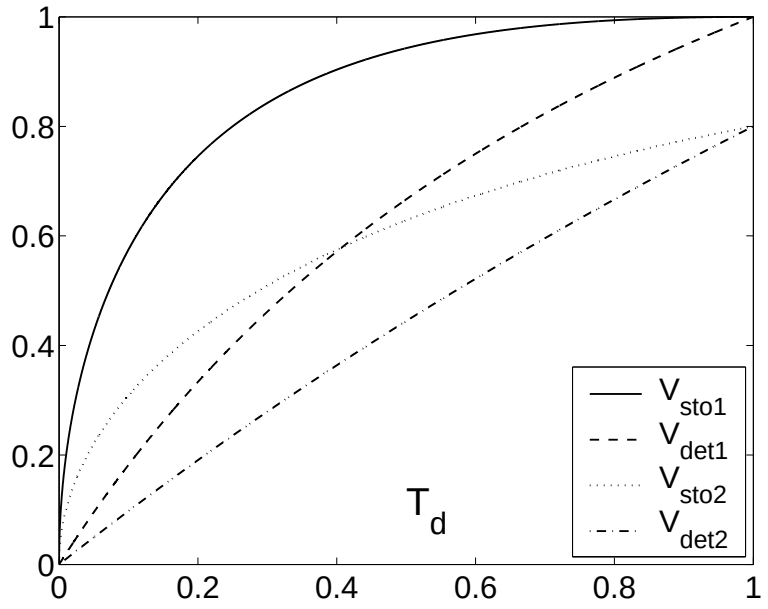

Figure 4. Visibilities of single and double loop interferometers. The visibilities V_{sto1} for stochastic (Eq.(11)) and V_{det1} for deterministic (Eq.(13)) absorption in a single loop interferometer are shown as a function of transmission probability T_d in beam path (d). In the double loop interferometer no phase shifter Δ_f and no absorber α_f is in beam path (f). In this case the visibilities V_{sto2} and V_{det2} of Eqs.(15) and (17) are smaller than in a single loop device.

$$V_{sto2} = \frac{4\sqrt{T_d}}{4+T_d} \; < \; 1 \quad . \tag{15}$$

The deterministic case may be expressed as

$$K_0 \propto |\, 2 + e^{ik_0\Delta_d}|^2 T_d + 4\,(\,1 - T_d) = T_d + 4\,[\,1 + T_d\, cos(\Delta_d k_0)] \quad , \tag{16}$$

$$V_{det2} = \frac{4\,T_d}{4+T_d} \; < \; 1 \quad . \tag{17}$$

In general, $V_{sto1} > V_{sto2}$ and $V_{det1} > V_{det2}$ for $0 \leq T_d \leq 1$ (Fig.(4)). An interesting case arises, if a phase shifter Δ_f (and no absorption α_f) is inserted in beam path (f). The intensity then becomes

$$\begin{aligned} K_0 &\propto |\, e^{ik_0\Delta_d - \alpha_d} + 1 + e^{ik_0\Delta_f}|^2 = \\ &= T_d + 2\,\sqrt{T_d}\,[cos(\Delta_d k_0) + cos(\Delta_d k_0 - \Delta_f k_0)] + 4\, cos^2(\Delta_f k_0/2) \quad . \end{aligned} \tag{18}$$

If $\Delta_f = 0$, then Eq.(18) reduces to Eq.(14). If $\Delta_f k_0 = (2n+1)\pi$, then $e^{i\Delta_f k_0} = -1$ and $K_0 \propto T_d$. If $2n\pi \leq \Delta_f k_0 \leq (2n+1)\pi$, maxima of K_0 are at $\Delta_d k_0 = \Delta_f k_0/2 + 2n\pi$ and minima at $\Delta_d k_0 = \Delta_f k_0/2 + (2n+1)\pi$. These maxima and minima are interchanged in the range $(2n+1)\pi \leq \Delta_f k_0 \leq (2n+2)\pi$, and it is not necessary to consider this case separately. One gets:

$$K_{0,\frac{max}{min}} \propto T_d \pm 4\, cos(\Delta_f k_0/2)[\sqrt{T_d} \pm cos(\Delta_f k_0/2)] \quad , \tag{19}$$

where the upper sign belongs to the maximum and the lower sign to the minimum intensity. The visibility is

$$V_{sto2\Delta_f} = \frac{4\sqrt{T_d}\,cos(\Delta_f k_0/2)}{4\,cos^2(\Delta_f k_0/2) + T_d} \quad . \tag{20}$$

If $\Delta_f k_0 = 0$, then $V_{sto2\Delta_f} = V_{sto2}$. If $\Delta_f k_0 = 2\pi/3$, then $V_{sto2\Delta_f} = V_{sto1}$. In particular we emphasize the fact that the maximum of the function $V_{sto2\Delta_f}$ is at $T_d = 4\,cos^2(\Delta_f k_0/2)$ where $V_{sto2\Delta_f} = 1$. For a given transmission T_d in beam path (d) a phase shift $\Delta_f k_0 = 2\,arccos(\sqrt{T_d}/2)$ in path (f) should be chosen in order to achieve a visibility of 1 (Fig.(5) and Fig.(6))! Setting $T_d = 1$ the relation $V_{sto2\Delta_f}$ of Eq.(20) reduces to a formula which already has been discussed in [3] (see Fig.(6)).

An analogous equation can be derived for the deterministic case which reads (Fig.(7))

$$V_{det2\Delta_f} = \frac{4\,T_d\,cos(\Delta_f k_0/2)}{4\,cos^2(\Delta_f k_0/2) + T_d} < 1 \quad , \; for \;\; T_d < 1 \;\; . \tag{21}$$

In case of deterministic visibility the value of 1 cannot be achieved for $T_d < 1$.

In order to compare intensities and to assess possibilities for measurements, Figs.(8a,b,c) present values of K_0 and K_G as a function of the phase shift $\Delta_d k_0$ in beam path (d). From these figures it can be concluded that in spite of strong absorption small signals can be measured with visibility 1 and with sufficient intensity by adequately adjusting the phase shifter in the second loop of the interferometer. However, as shown in the next section, the described procedure specifies an ideal situation and there is a limit for measuring weak signals using such a technique.

4. Discussion and conclusion

In this paper some intensity and visibility aspects of a double loop neutron interferometer have been considered. In the first part the wave functions of a triple wave function superposition in the forward and diffracted direction behind the interferometer has been described using the theory of dynamical diffraction in single crystals. Phase shifters and absorbers have been taken into account. In general the intensity levels of the forward and diffracted beams are different. Under certain circumstances these levels can be made equal using various absorbers. This is an interesting new aspect because in this case the device can be regarded as a 50/50 beam splitter. This feature is not possible in a single loop interferometer.

In the second part the visibility has been investigated. As an another important new result it has been shown that a visibility value of 1 may be reached when the transmission T_d (for stochastic absorption processes) in the first loop is adjusted accordingly to the phase shift $\Delta_f k_0$ in the second loop:

$$T_d = 4cos^2(\Delta_f k_0/2) \quad \rightarrow \;\; V_{sto2\Delta_f} = 1. \tag{22}$$

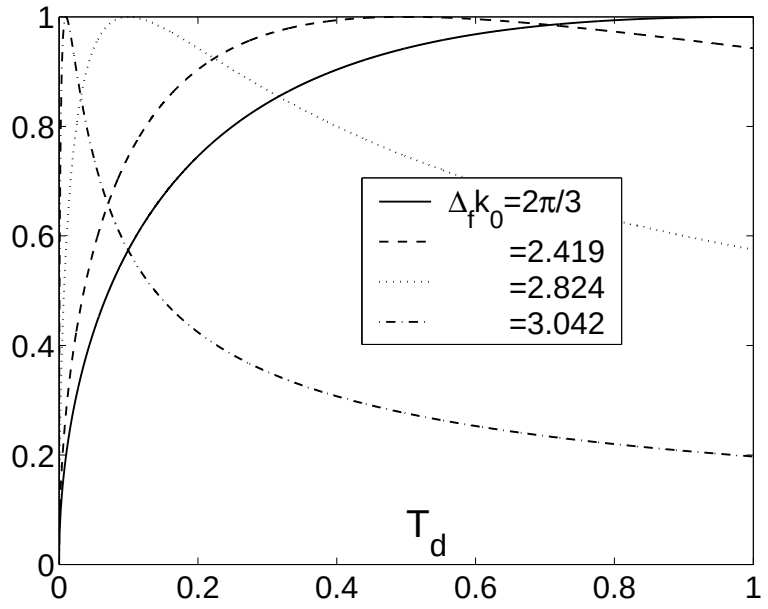

Figure 5. Visibility $V_{sto2\Delta_f}$ (Eq.(20)) in a double loop interferometer as a function of transmission probability T_d in beam path (d). A phase shift $\Delta_f k_0$ is applied in beam path (f). The visibility attains the value 1 for $T_d = 4\,cos^2(\Delta_f k_0/2)$.

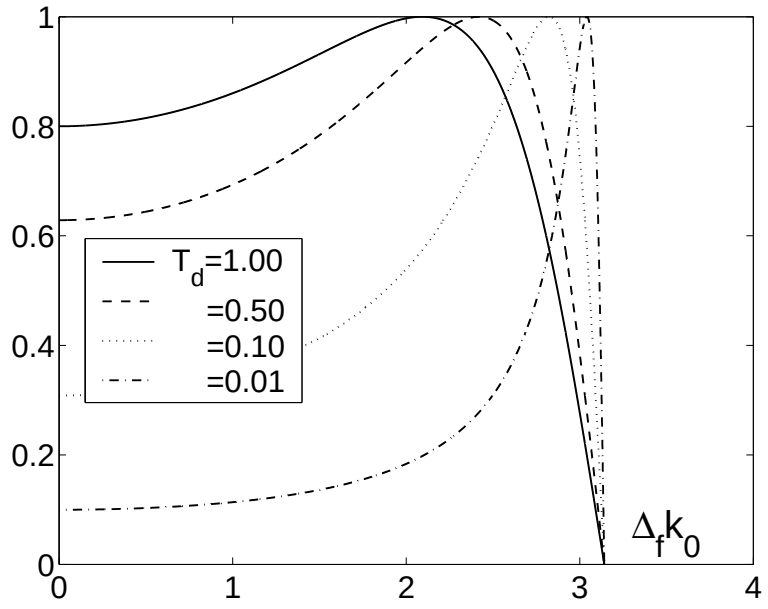

Figure 6. Visibility $V_{sto2\Delta_f}$ (Eq.(20)) in a double loop interferometer as a function of phase shift $\Delta_f k_0$ in beam path (f). A transmission probability T_d is applied in beam path (d). The visibility attains the value 1 for $T_d = 4\,cos^2(\Delta_f k_0/2)$, where the 4 parameters T_d correspond to those 4 parameters $\Delta_f k_0$ in Fig.(5) via this equation.

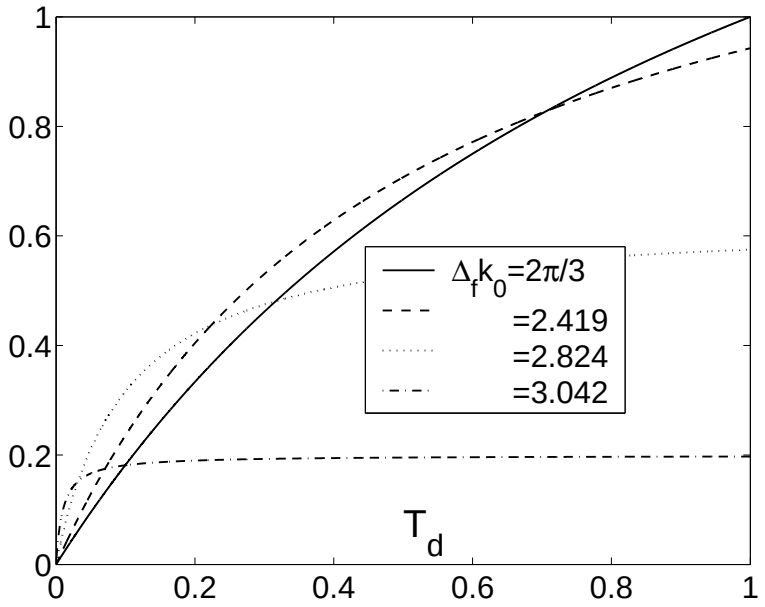

Figure 7. Visibility $V_{det2\Delta_f}$ (Eq.(21)) in a double loop interferometer as a function of transmission probability T_d in beam path (d). A phase shift $\Delta_f k_0$ is applied in beam path (f). Contrary to $V_{sto2\Delta_f}$ this function $V_{det2\Delta_f}$ cannot attain a value of 1 for $T_d < 1$.

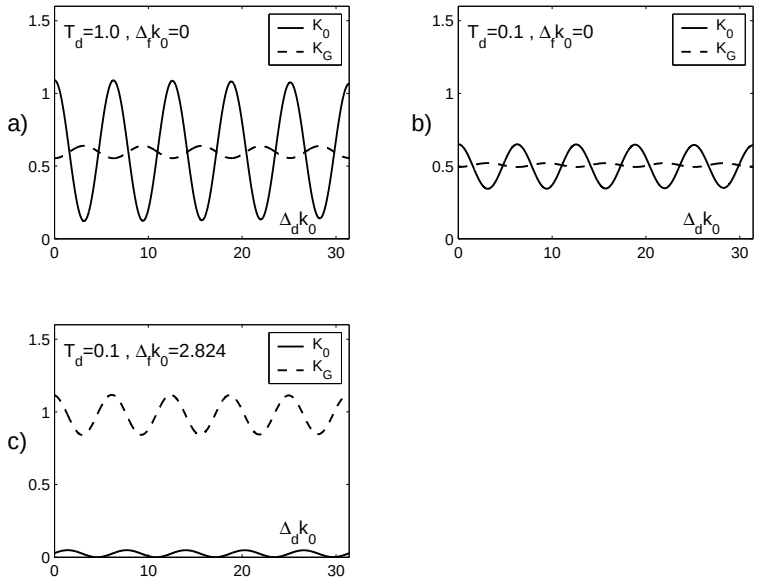

Figure 8. Intensities K_0 and K_G behind the double loop interferometer (see Fig.(1)) as a function of the phase shift $\Delta_d k_0$ in beam path (d). a) No absorption in beam (d) ($T_d = 1$) and no phase shift in beam (f) ($\Delta_f k_0 = 0$). Fig.(8a) can be compared to Fig.(2). Note that in Fig.(8a) the intensities K_0 and K_G are plotted as a function of $\Delta_d k_0$. b) Absorption in beam (d) (transmission $T_d = 0.1$) and no phase shift in beam (f). The intensities have been attenuated accordingly. c) $\Delta_f k_0 = 2.824$ has been chosen. This value corresponds to $T_d = 0.1$ (see Figs.(5) and (6)). K_0 shows a visibility of 1 because of $I_{min} = 0$.

$T_d = e^{-2\alpha_d}$ is the transmission probability in beam (d) (α_d is the absorption coefficient) and Δ_f is the phase shift in beam (f), where - according to Fig.(1) - the intensity K_0 in the forward direction behind the double loop interferometer oscillates as a function of the phase shift Δ_d in beam (d). Using the described method in principle every signal in path (d) can be transformed to a signal K_0 with visibility 1 and therefore the method could be most interesting for small signals.

It should be noted that to describe real experimental situations an additive term I_{incoh} must be introduced in Eq.(18) to represent the incoherent part of the intensity (background intensity). The main reason for the incoherent effects is non - interference because of crystal imperfection (not absolute parallelism of the crystal lattice planes throughout the interferometer) as well as lattice vibrations and small temperature gradients. The term I_{incoh} leads to a new visibility $V'_{sto2\Delta_f}$:

$$V'_{sto2\Delta_f} = \frac{4\sqrt{T_d}\,cos(\Delta_f k_0/2)}{4\,cos^2(\Delta_f k_0/2) + T_d + I_{incoh}} \quad . \tag{23}$$

This expression is always less than 1 for $I_{incoh} > 0$ (see also Eq.(22)). In order to measure weak signals (see Fig.(8c)) the background intensity has to be as small as possible. This could be a serious constraint considering real experimental conditions using neutrons. It should be mentioned that the background intensity has no influence on Eq.(8) concerning the 50/50 beam splitter system. Note also that an additional empty phase which is a signature of an interferometer does not affect the aforementioned considerations about the intensity and visibility.

It is a common problem in signal processing to measure weak signals. The absorber serves only to generate these signals. In spite of the constraints mentioned above for almost ideal experimental situations Eq.(22) predicts a visibility close to 1. This could also be the case in systems of Mach - Zehnder interferometers using laser beams. Here the number of counts registered in a detector in a certain time interval obeys a Poisson distribution with variance $(\Delta N)^2 = \bar{N}$, where $\bar{N}$ is the mean number of counts. The Poisson distribution is a signature of coherent state behavior. For small count rates the described method may be used to measure small signals with visibility 1.

The system can easily be adapted (loop B in Fig.(1)) to an eight-port interferometer as a high sensitive homodyne detection setup [4,7,8] as shown in Fig.(9). In this case two vacuum inputs $|0>$ have to be added and the strong local oscillator limit can be applied to the idler beam (a) when the signal beam (e) is relatively strongly attenuated by an absorber α_e. Homodyne detection in laser interferometry is a method, in which the field amplitudes (the quadrature components) are measured instead of the quantized intensity. The balanced version of homodyne detection has a great practical advantage of cancelling technical noise and the classical instabilities of the reference field. Thereby the signal interferes with a coherent laser beam at a well-balanced 50/50

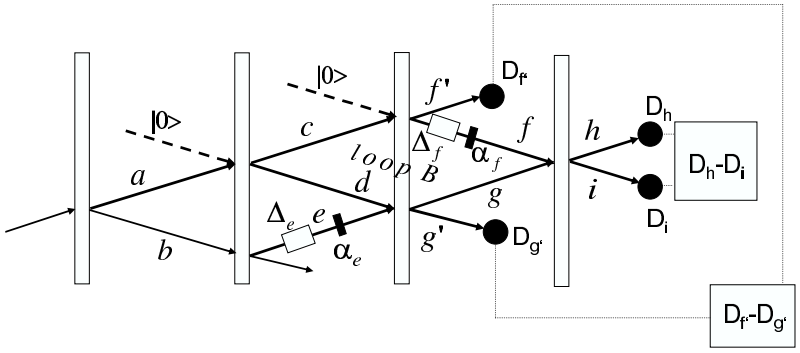

Figure 9. An eight-port interferometer is built up from loop B in Fig.(1). Neutron count rate differences can be measured by the detectors D_h and D_i as well as $D_{f'}$ and $D_{g'}$. The phase of the strongly attenuated signal beam (e) can be modified by a phase shift Δ_e. The strong local oscillator is given by the idler beam (a).

beam splitter. It provides the phase reference for the quadrature measurement. The intensity difference is the quantity of interest because it contains the interference term of the local oscillator and the signal.

Finally, as already mentioned above, we would like to point out again that there are good reasons to assume that a similar result can be attained in double Mach-Zehnder interferometry where photonic beams in fiber glass are used. As a visibility near to 1 is of great advantage for measuring largely attenuated beams, our approach outlines a general method to investigate weak signals in double loop interferometric devices.
